Abstract: Static var compensator (SVC) as one component of flexible Ac transmission systems (FACTS) device. Play an important role in controlling reactive power flow to power network. Because of economic consideration identifying the best location for installing the SVC is also important. This paper discusses the optimal allocation and size of static var compensator to improve voltage magnitude for a power system. National grid of Sudan (NGS) transmission lines-500KV is used as case study. Solution is obtained using Neplan software. The results show the optimal allocation is in the kabashi bus with size of 90.392MVAR.

Keywords: Static var compensator (SVC), National grid of Sudan (NGS), flexible Ac transmission systems (FACTS) device.

1. INTRODUCTION

The concept of using solid-state power electronic converters for power flow control at transmission level has been known as FACTS. The idea has had some success in certain areas such as reactive power dispatch and control. However, the full use of FACTS for power flow control has had limited applications in part due to reliability concerns and in part due to availability of components. Perhaps the most salient consideration is the cost of these devices. A potential motivation for accelerated use of FACTS is the deregulation/competitive environment in contemporary utility business. The potential ability of controlling the flow of electric power, and the ability to effectively join electric power networks that are not strongly interconnected, suggest that the FACTS may find new applications [2].

Power electronics based equipment, or FACTS, provide proven technical solutions to voltage stability problems. Especially, due to the increasing need for fast response for power quality and voltage stability. Static Var Compenators (SVC) has become feasible Alternatives to a fixed reactive source, and therefore have received intensive interests [2].

2. STATIC Var COMPENSATOR (SVC)

The Static VAr Compensator (SVC) today is considered as a very mature technology. It has been used for reactive power compensation since the 1970s. A SVC is a shunt connected FACTS device whose output can be adjusted to exchange either capacitive or inductive currents to the connected system. This current is controlled to regulate specific parameters of the electrical power system (typically bus voltage) [3]. The thyristor has been an integral part in realizing the SVC and to enable control of its reactive power flow. It is used either as a switch or as a continuously controlled valve by controlling the firing angle. It should be noted that the SVC current will contain some harmonic content, something that needs attention design process [3].

2-1 Advantages of SVC

The main advantages of SVCs over simple mechanically switched compensation schemes are their near-instantaneous response to change in the system voltage. For this reason, they are often operate at close to their zero-point in order to maximize the reactive power correction. The of SVC use have the following profits [4]:
1. Improves system steady-state stability.
2. Improves system transient stability.
4. Reduces voltage drops in load areas during severe disturbances.
5. Reduces transmission losses.

2-2 SVC Elements:

This section presents the different “building blocks” that are commonly used when designing an SVC. The components are presented individually to describe their influence on the grid. We will also briefly discuss some of the problems associated with the components and how these could be handled. This is done to give some insight into how an SVC operates [3]. The different building blocks presented in this section are illustrated in figure 1.
3. VOLTAGE STABILITY

Voltage stability can also be called “load stability”. A power system lacks the capability to transfer an infinite amount of electrical power to the loads. The main factor causing voltage instability is the inability of the power system to meet the demands for reactive power in the heavily stressed systems to keep desired voltages. Other factors contributing to voltage stability are the generator reactive power limits, the load characteristics, the characteristics of the reactive power compensation devices and the action of the voltage control devices [10]. Voltage collapse typically occurs in a power system, which is heavily loaded, faulted and/or has reactive power shortages. Voltage collapse is a form of system instability that involves mapower system components and their variables simultaneously. Voltage collapse often involves the entire power system, although it usually has a relatively larger involvement of one particular area of the power system [11].

4. VOLTAGE STABILITY INDICES

The purpose of voltage stability indices is to determine the point of voltage instability, the weakest bus in the system and the critical line referred to a bus. These indices are referred to either a bus or a line [12]:

i. P-V Curve
As the power transfer increases, the voltage at the receiving end decreases. Finally, the critical or nose point is reached. It is the point at which the system reactive power is out of use. The curve between the variation of bus voltages with loading factor ($\lambda$) is popularly called as P-V curve or ‘Nose’ curve. PV curves are used to determine the loading margin of the power system. The margin between the voltage collapse point and the current operating point is used as voltage stability criterion [12].

ii. Q-V Curve
With the help of Q-V curve, it is possible for the operators, to know the maximum reactive power that can be added to the bus before reaching minimum voltage limit. The MVAr distance from the operating point to the bottom of the Q-V curve is called as the reactive power margin. Q-V curve can be used as an index for voltage stability limit.

V/Vn Index
The ratio V/Vn at each bus shows the voltage stability map of the system. V is the bus voltage at certain load obtained from load flow study. Voltages Vn are obtained by solving load flow of the system at an identical state but with all the loads set to zero. This index allows immediate detection of weakest bus and corrective action can be taken to prevent the voltage instability [12].

iii. L-index
In order to become of practical value the indicator L has to be extended to the multi-node system, there are two categories of nodes which have to be distinguished. One is characterized by the behavior of the PQ-node which stands for a type of consumer node, the other comprise the generator nodes which may be given by a PV-node or by the slack node.

5. NGS TRANSMISSION LINES-500KV (CASE STUDY)

NGS transmission lines-500Kv data are presented in table (1) below, where the single line diagram is in figure (2).

6. SIMULATION RESULTS

Simulation for the case study is done using NEPLAN software with loading point (λ) equal to 1.2 of the total connected load. The voltage magnitude is calculated without SVC and with it. The results are obtained by installing SVC in two different places (Kabashi busbar and Markhiat busbar) as shown in table 2. The results show SVC can be used to improve voltage magnitude cheaper, higher capacity, faster, and more reliable than dynamic compensation schemes such as synchronous condensers. Voltage profile is improved for the NGS 500kv transmission lines using SVC. The optimal allocation, is achieved by installing SVC in kabashi busbar with size of 90.392 MVAr.
